Abstract. The relationship between spreading and stretching directions is investigated at oblique-spreading oceanic ridges using earthquake focal mechanisms. The stretching direction at ridge axes corresponds to the direction of the greatest principal strain ε_1 taken as the mean trend of the seismic T-axes of extensional earthquake focal mechanisms. It is compared with the spreading direction provided by global plate-motion models. We find that the stretching direction trends approximately halfway between the spreading direction and the normal to the ridge trend, a result in line with analogue experiments of oblique rifting. This result is satisfactorily accounted for with an analytical model of oblique rifting, for which the direction of ε_1 is calculated with respect to rifting obliquity for different amounts of stretching using continuum mechanics. For low stretching factors, typical of incremental seismic deformations, ε_1 obliquity is two times lower than rifting obliquity. For higher stretching factors, the stretching and spreading directions become parallel.

Keywords: oblique rifting, oblique-spreading ridges, stretching, extension

1. **Introduction**

Determining the direction of relative motion between two rigid plates on either side of a deformation zone can be achieved by analysing the strain within the deformation zone. In oblique deformation settings, i.e., when the direction of displacement between the two rigid plates is oblique to the deformation zone, the direction of relative motion is generally not parallel to the principal strain directions (e.g., Sanderson and Marchini, 1984; Tikoff and Teyssier, 1994; Dewey et al., 1998; Fossen and Tikoff, 1998). This result is for example the case at the axial rifts of oblique-spreading mid-oceanic ridges (Taylor et al., 1994; Tuckwell et al., 1996), which are investigated in this paper.

The process of oblique divergence between two tectonic plates often involves the formation of an oblique rift. Oblique rifting occurs in the continental domain (e.g. Lake Baikal; Petit et al, 1996) as well as in the oceanic domain at the axis of slow-spreading ridges (e.g., Southwest Indian Ridge). The faulting and strain patterns associated with oblique rifting have been investigated for both oceanic and continental rifts (Dauteuil and Brun, 1993, 1996; Murton and Parson, 1993; Shaw and Lin, 1993; Taylor et al., 1994; Applegate and Shor, 1994; Carbotte and Mac Donald, 1994; McAllister et al., 1995; Dauteuil et al., 2001; Acocella and Korme, 2002; Clifton and Schlische, 2003; Fournier et al., 2004a), and by means of experimental (Withjack and Jamison, 1986, Tron and Brun, 1991; Dauteuil and Brun, 1993; McClay and White, 1995; Bonini et al., 1997; Clifton et al., 2000; Mart and Dauteuil, 2000; Clifton and Schlische, 2001; Venkat-Ramani and Tikoff, 2002), analytical (Elliot, 1972; Sanderson and Marchini, 1984; McCoss, 1986; Withjack and Jamison, 1986; Fossen and Tikoff, 1993; Tikoff and Fossen, 1993, 1998; Krantz, 1995; Tuckwell et al., 1996; Abelson and Agnon, 1997), and numerical (Tuckwell et al., 1998) models. These studies show that oblique rifting is accommodated by both normal and strike-slip faults, whose relative proportions and orientations depend on rifting obliquity defined as the angle between the normal to the rift trend and the direction of displacement. Oblique rifting typically produces en echelon fault patterns that are not perpendicular to the direction of relative motion.

Withjack and Jamison (1986) demonstrated, with analogue clay models marked at their surface by deformed circles, that three structural directions are linked in the process of oblique rifting: the rift trend (or its perpendicular), the direction of relative motion between the two plates, and the trend of the greatest principal strain axis ε_1 of the finite strain ellipsoid (Figure 1). When the direction of relative motion is perpendicular to the rift trend, the rift formation involves pure shear extension without simple shear and the deformation is accommodated by dip-slip normal faults parallel to the rift. The ε_1 axis is then horizontal, perpendicular to the normal faults, and parallel to the direction of divergence. When the relative motion is oblique to the rift trend, i.e., in transtensional settings, the rift formation involves a combination of pure shear extension and simple shear. The deformation is accommodated by a combination of normal faults parallel and oblique to the rift trend, and also by strike-slip faults when the rifting obliquity increases. In this case, ε_1 is approximately bisector of the angle between the displacement vector and the normal to the rift (Withjack and Jamison, 1986). The analytical solution to the problem of oblique rifting, based on the general theory of transpression-transtension developed by Sanderson and Marchini (1984) and Tikoff and Teyssier (1994), confirms that the infinitesimal extension direction is exactly the bisector of the angle between the displacement vector and the normal to the rift (see also McCoss, 1986).

Tron and Brun (1991) and Clifton et al. (2000) showed with laboratory experiments that the fault strike distribution in oblique rifts depended on the rifting obliquity. Consequently, a statistical analysis of fault strikes in natural rifts may provide an accurate estimate of the direction of divergence. This rule has been applied successfully to determine the direction of spreading along two slow-spreading ridges, the Mohns Ridge in the North Atlantic Ocean (Dauteuil and Brun, 1993) and the West Sheba Ridge in the Gulf of Aden (Dauteuil et al., 2001), and the kinematic evolution of the Okinawa Trough (Sibuet et al., 1995, Fournier et al., 2001a). Taylor et al. (1994) and Tuckwell et al. (1996) examined the relationship between the orientation of extensional fractures and the plate motion vector at oblique spreading ridges and at so-called “extensional transform zones” (ETZ) characterized by an obliquity between

45° and 75° (Taylor et al., 1994). They observed that, at oblique spreading ridges, most normal faults form at an angle with the ridge axis approximately equal to the half of the plate motion obliquity, a result in line with the experiments of Withjack and Jamison (1986), Tron and Brun (1991), and Clifton et al. (2000).

However, with the exception of the work of Withjack and Jamison (1986), these studies mainly focused on fault strikes and did not regard the implications in terms of strain. In experimental models as well as in the offshore domain, statistical analysis of fault distributions does not allow estimation of strain axes directions because slip vectors on fault planes cannot be directly observed. In seismically active rifts, however, the direction of maximum stretching can be inferred from earthquake focal mechanisms. In the following, we investigate the relationship between spreading and stretching directions as determined from earthquake focal mechanisms at six oblique spreading ridges.

2. Stretching direction determined from earthquake focal mechanisms

In a homogeneous and isotropic material, rupture occurs on two conjugate planes of maximum shear stress oriented with respect to the maximum and minimum stresses σ_1 and σ_3. Because most earthquakes occur on pre-existing faults, earthquakes do not provide direct evidence for the orientation of principal stresses, but instead provide evidence for the orientation of the strain axes (e.g., Twiss and Unruh, 1998). The compression (P) and tension (T) axes of the double-couple focal mechanism solutions are defined kinematically by fault slip and correspond to the principal strain axes ε_3 and ε_1, respectively. They represent the principal axes of the incremental (or instantaneous) strain tensor for fault movements (e.g., McKenzie, 1969; Marrett and Allmendinger, 1990). Thus, in extensional settings, T-axes of normal faulting earthquakes can be used to determine the direction of stretching. This method is applicable in regions of homogeneous deformation, i.e. when focal mechanisms are all of the same type, which is the case at spreading centres of oceanic ridges.

3. Stretching vs spreading directions at oblique spreading ridges

In the oceanic domain, rifting occurs at the crest of slow-spreading mid-oceanic ridges characterised by high seismic activity. Fast spreading centres are devoid of an axial rift and seismicity, and are characterized by orthogonal spreading except in a few back-arc basins where ETZ have been described, such as the Manus and Lau basins (Taylor et al., 1994). At fast spreading ridges, the obliquity between the spreading direction and the plate boundary is taken up by transform faults (e.g., Pacific-Antarctic Ridge). The main oblique-spreading ridges on Earth are the Southwest Indian Ridge (SWIR) in the Indian Ocean (Figure 2; Ewing and Heezen, 1960; Fisher and Sclater, 1983; Patriat, 1987), the Sheba Ridge in the Gulf of Aden (Figure 3; Matthews et al., 1967; Laughton et al., 1970), and the Reykjanes (Figure 4; Vine, 1966), Mohns (Figure 5; Talwani and Eldholm, 1977), and Knipovich (Figure 5; Vogt et al., 1979; Okino et al., 2002) ridges in the North Atlantic Ocean. These five ridges have been surveyed together with the Carlsberg Ridge in the northwest Indian Ocean (Figure 3; Schmidt, 1932; Vine and Matthews, 1963), which is generally considered as a type example of orthogonal-spreading ridge.

We have selected in the Harvard centroid moment tensor (CMT) catalog all focal mechanisms of earthquakes shallower than 50 km which occurred between 1976 and 2000 (25 years) along these six ridges (Dziewonski et al., 1981). 271 mechanisms of extensional or strike-slip type have been obtained and are plotted in Figures 2 to 5. For each ridge or ridge segment, we determined its mean trend, the mean spreading direction, and the mean stretching direction (Table 1). If necessary, the ridges have been divided in roughly rectilinear segments. For example, the SWIR has been divided into two parts: the northeastern part strikes N54°E on average and the southwestern part N105°E (Figure 2). The ridge mean trend has been directly measured on bathymetric and seismic maps. The mean spreading direction corresponds to the average of the spreading directions calculated at the ridge segment extremities from the NUVEL-1A plate motion model (DeMets et al., 1990; 1994), except for Sheba and Carlsberg ridges for which we used Fournier et al. (2001b) solution (Table 1). The mean stretching direction is computed from the normal faulting solutions (inserts in Figures 2 to 5). From these data, the spreading and stretching obliquities have been calculated for each

135 ridge (Table 1). Strike-slip focal mechanisms along transform faults are also plotted in
136 Figures 2 to 5 to show the consistency between slip vectors of strike-slip mechanisms and
137 spreading directions provided by plate motion models.

138 The stretching obliquity (S_{obl}) is plotted against spreading (or rifting) obliquity (R_{obl}) for
139 the selected ridges in Figure 6. Spreading obliquities greater than 45° are never observed
140 along slow-spreading ridges. The points plot along the $S_{obl} = R_{obl} / 2$ line for spreading
141 obliquities less than 30° (Carlsberg, southwerstern SWIR, Reykjanes, and Knipovich ridges),
142 and slightly depart from this line for obliquities between 30° and 45° (Mohns, northeastern
143 SWIR, and Sheba ridges).

144

145 **4. Analytical model of oblique rifting**

146 A horizontal plane-strain model of oblique rifting is presented in Figure 6a. A unit
147 length of lithosphere (initial rift) is obliquely extended to a length β measured perpendicularly
148 to the rift axis. β thus defines a stretching factor corresponding to the ratio of the final versus
149 initial length (e.g., McKenzie, 1978). The stretching obliquity, defined as the angle between
150 the normal to the rift trend and greatest principal strain axis of the strain ellipse (ε_1), is
151 calculated as a function of the rifting obliquity and β.

152 The finite strain ellipse is calculated from continuum mechanics by decomposing the
153 deformation matrix (deformation gradient tensor) in finite strain (shape and orientation of the
154 strain ellipse in 2D) and finite rotation of the principal strain axes (e.g., Elliot, 1972; Jaeger
155 and Cook, 1979; McKenzie and Jackson, 1983; Fournier et al., 2004b). The eigenvalues and
156 eigenvectors of the finite strain matrix provide the length and orientation of the principal axes
157 of the finite strain ellipse. Exactly the same result is obtained by factorization of the
158 deformation matrix into pure shear and simple shear components (e.g., Sanderson and
159 Marchini, 1986; Tikoff and Fossen, 1993; Fossen and Tikoff, 1993; Tikoff and Teyssier,
160 1994; Krantz, 1995; Fossen and Tikoff, 1998).

161 The strain ellipse resulting from oblique rifting is shown as a function of the rifting
162 obliquity for various values of stretching factor β in Figure 6b. For a given rifting obliquity,

163 the principal strain axes progressively rotate as β increases. For a rifting obliquity of 45°, the
164 stretching obliquity increases from 24° for $\beta = 1.1$ to 36° for $\beta = 3$. Furthermore, for a
165 given β, the stretching obliquity increases as the rifting obliquity increases. For example, for
166 $\beta = 2$, the stretching obliquity increases to 10° to 20°, 32°, 45°, and 63° for rifting obliquity
167 of 15° to 30°, 45°, 60°, and 75°, respectively.

168 In Figure 6c, the stretching obliquity is plotted against rifting obliquity for various
169 values of β. When β is small ($\beta < 1.1$), the stretching obliquity is equal to the half of the
170 rifting obliquity ($S_{obl} = R_{obl} / 2$). With increasing strain ($\beta > 5$), the stretching obliquity
171 becomes almost equal to the rifting obliquity ($S_{obl} = R_{obl}$).

172

173 **5. Discussion**

174 These predictions can be compared with the results obtained for the selected oblique-
175 spreading ridges (Figure 6). For most ridges, the ε_1 direction ranges along the $S_{obl} = R_{obl} / 2$
176 line, which corresponds to a low amount of extension in the model. A simple interpretation is
177 that rocks of the Earth's upper crust undergo small strains of a few per cent before brittle
178 failure occurs and relieves the accumulated strain. The principal strain directions deduced
179 from earthquake focal mechanisms thus represent the infinitesimal (or instantaneous) strain
180 ellipsoid.

181 Our results can also be compared with those of Taylor et al. (1994) and Tuckwell et al.
182 (1996) for the Reykjanes, Mohns, Southwest Indian (NE), and Sheba ridges, provided one
183 converts their α and ϕ angles into rifting and stretching obliquities:

184
$$R_{obl} = 90 - \alpha$$
$$S_{obl} = \phi - \alpha$$

185 In contrast with us, Taylor et al. (1994) and Tuckwell et al. (1996) defined the stretching
186 direction as the perpendicular to the mean trend of normal faults in extension zones.

187 We find a very good agreement for the Reykjanes Ridge, where our estimates of
188 spreading and stretching obliquities differ only by 1° and 4°, respectively, which is smaller
189 than the uncertainties. For the Mohns Ridge, our results compare well with those of Taylor et

al. (1994) but slightly differ from Tuckwell et al. (1996) estimates of spreading obliquity (34±8° vs 40±6°), mainly because we (and Taylor et al., 1994) use a different azimuth of spreading (N119°E vs N110°E). Despite this, we find no large discrepancies between our estimates of stretching obliquity and theirs. Much larger differences are found for the Southwest Indian and Sheba ridges: for the former, whereas Taylor et al. (1994) and Tuckwell et al. (1996) give comparable values of 14° and 23-27° for stretching and spreading obliquities, we find 29±7° and 42±11°, respectively. These differences are entirely attributable to different estimates of ridge trend and spreading directions, due to the fact that Taylor et al. (1994) and Tuckwell et al. (1996) took into account only a small part of the SWIR located near the Rodrigues triple junction (26°N; Mitchell, 1991), whereas we have taken into account all the northeastern part of the SWIR over several thousands kilometres (Figure 2). However, here again, the determination of stretching directions from earthquake focal mechanisms gives results comparable to the analysis of normal fault trends. Concerning the Gulf of Aden (Sheba Ridge), a difference up to 5-10° exists between our values and those of Taylor et al. (1994) and Tuckwell et al. (1996). Once again, these differences come from the selection of different study areas. The results of Taylor et al. (1994) and Tuckwell et al. (1996) concern the westernmost part of the Sheba Ridge near the Gulf of Tadjura (45°E; Tamsett and Searle, 1988), whereas our results encompass the entire ridge from 46°E to 56°E (Figure 3; Table 1). Hence, the differences between our results and those of Taylor et al. (1994) and Tuckwell et al. (1996) come from different scales of study. Studying normal fault strikes at ridge axes requires detailed mapping of fault fabrics. Working with focal mechanisms from the world seismicity catalogs allows surveying of larger areas.

In general, the results of Tuckwell et al. (1996) show that most values of stretching vs rifting obliquities range along the $S_{obl} = R_{obl} / 2$ line, like in the present study. Surprisingly, the direction of ε_1 deduced from infinitesimal strain (earthquakes) does not differ from the perpendicular to the normal faults, which are markers of finite strain and can have accommodated a significant amount of deformation. This result suggests that normal faults initially form perpendicular to the direction of ε_1 of the infinitesimal strain ellipsoid, keep this

orientation during ongoing extension, and do not significantly rotate as the strain increases. As oblique slip (characterized by oblique focal mechanisms) is seldom observed, this implies that normal faults at ridge axes only accommodate a small amount of deformation during the time when they are located in the seismically active part of the rift (about 2 Ma for a ridge with a half-spreading rate of 5 mm/yr and a 20 km large axial rift).

6. Conclusion

Plate-motion models such as RM2 and NUVEL-1 (Minster and Jordan, 1978; DeMets et al., 1990) did not account for slip vectors of extensional focal mechanisms along oceanic ridges. The first reason was of course that, for extensional mechanisms, it is not possible to determine which of the two nodal planes is the fault plane and which is the actual slip vector. The second reason was that at oblique-spreading ridges, slip vectors are not parallel but oblique to the plate relative motion. Here, we demonstrate that, at slow-spreading oblique ridges, the maximum strain axis determined from earthquake focal mechanisms trends halfway between the direction of spreading and the normal to the ridge. Hence, the kinematics of oblique ridges and rifts can possibly be determined from a set of extensional focal mechanisms, without assumption on the fault plane and the slip vector. This result could be useful in continental rifts where transform faults are not developed and plate kinematics difficult to assess. The comparison with an analytical model of oblique rifting shows that these features correspond to small deformations at ridge axes, which is consistent with the fact that earthquakes represent infinitesimal strains. Furthermore, the analysis of normal faults directions (Taylor et al., 1994; Tuckwell et al., 1996) yields similar conclusions, though normal fault heaves represent thousands of co-seismic slips. Yet, compared to the rift width (~10 to 20 km), the cumulated stretching factor on each fault must remain low.

Figure captions

Figure 1. Geometrical relationship between the main structural directions at oblique rifts.

Figure 2. Bathymetric map (Sandwell and Smith, 1997), shallow seismicity between 1964 and 1995 (focal depth < 50 km; magnitude > 2; Engdahl et al., 1998), and all available earthquake focal mechanisms (Harvard CMT for the period 1976-2000; Dziewonski et al., 1981) for the Southwest Indian Ridge (SWIR). Inserted stereoplots are equal-area projections of the P and T axes of the extensional focal mechanisms and the mean direction of extension (ε_1). The SWIR has been divided into two parts with different trends: the northeastern part between the Rodrigues triple junction and the Prince Edward-Marion-Andrew Bain fracture zone (PEMABFZ; Grindlay et al., 1998) trends N054°E ±2°, and the southwestern part between PEMABFZ and 53°S, 14°E trends N105°E ±2°. Bathymetric contour interval is 1000m. Strike-slip focal mechanisms along fracture zones show the consistency between slip vector azimuths and directions of relative motion (solid arrows) calculated from plate motion models.

Figure 3. Same legend as Figure 2 for the Sheba and Carlsberg ridges. OTF is Owen transform faults. Bathymetric contour interval is 500m.

Figure 4. Same legend as Figure 2 for the Reykjanes Ridge. Between 55.5°N, 35.5°W and 63.5°N, 24°W, the ridge strikes N037°E ± 3°. Bathymetric contour interval is 500m.

Figure 5. Same legend as Figure 2 for the Mohns and Knipovich ridges (location in Figure 4). The Mohns Ridge strikes N063°E ± 2° on average between 71°N, 7.5°W and 73.5°N, 8°E The mean trend of the Knipovich Ridge between 73.7°N, 9°E and 78°N, 8°E is N178°E ± 2°. Bathymetric contour interval is 200m.

Figure 6. Stretching obliquity S_{obl} (maximum principal strain ε_1) as a function of spreading obliquity R_{obl} in degrees for seven oblique-spreading ridges. Data sources and abbreviations are given in Table 1. See text for additional explanation. Error bars for spreading obliquity represent the sum of the uncertainties in the measurement of the ridge mean trend and in the azimuth of spreading calculated along the ridge. Error bars for stretching obliquity represent the standard deviation of the T-axes azimuth.

Figure 7. a. Plane-strain analytical model of oblique rifting. See text for additional explanation. b. Strain ellipse for various stretching factors and rifting obliquities. c. Stretching obliquity S_{obl} as a function of rifting obliquity R_{obl} in degrees. The curves are calculated from the analytical model and the straight lines correspond to $S_{obl} = R_{obl}$ and $S_{obl} = R_{obl} / 2$.

Table

Table 1. Mean trend, azimuth of spreading, spreading obliquity, and principal strain ε1 obliquity for oblique spreading ridges

Ridge	Ridge mean trend	Ridge extremities			Mean azimuth of spreading	Mean T-axis Strike, Dip	Spreading obliquity	Principal strain ε1 obliquity	Labels[2]
		Latitude	Longitude	Azimuth of spreading[1]					
	(°E)	(°N)	(°E)	(°E)	(°E)	deg	deg	deg	
Aden - Sheba	N077°E ±3°	12 14.5	46 56	33 23	028 ±5	011, 1 (n=14)	41 ±8	24 ±8	SHE
Carlsberg	N135°E ±2°	10 4	57 63	31 35	033 ±2	219, 0 (n=18)	12 ±4	6 ±7	CAR
SWIR NE	N054°E ±2°	-45 -26	35 69	15 177	006 ±9	353, 3 (n=59)	42 ±11	29 ±7	SWN
SWIR SW	N105°E ±2°	-52 -53	14 28	34 22	028 ±6	202, 4 (n=21)	13 ±8	7 ±7	SWS
Reykjanes	N037°E ±3°	55.5 63.5	-35.5 -24	95 102	098 ±3	294, 2 (n=26)	29 ±6	13 ±8	REY
Mohn	N063°E ±2°	71 73.5	-7.5 8	113 125	119 ± 6	131, 4 (n=12)	34 ±8	22 ±7	MOH
Knipovitch	N178°E ±2°	73.7 78	9 8	126 128	127 ±1	104, 4 (n=7)	29 ±3	16 ±7	KNI

n is the number of extensional earthquake focal mechanisms used to determined the mean T-axes azimuth.

[1]Azimuths of spreading after DeMets et al. (1990), except for SHE and CAR after Fournier et al. (2001).

[2]Labels are for data plotted in Figure 5.
